

The RADStack: Open Source Lambda Architecture for Interactive Analytics

ABSTRACT

The Real-time Analytics Data Stack, colloquially referred to as the RADStack, is an open-source data analytics stack designed to provide fast, flexible queries over up-to-the-second data. It is designed to overcome the limitations of either a purely batch processing system (it takes too long to surface new events) or a purely real-time system (it's difficult to ensure that no data is left behind and there is often no way to correct data after initial processing). It will seamlessly return best-effort results on very recent data combined with guaranteed-correct results on older data. In this paper, we introduce the architecture of the RADStack and discuss our methods of providing interactive analytics and a flexible data processing environment to handle a variety of real-world workloads.

1. INTRODUCTION

The rapid growth of the Hadoop[16] ecosystem has enabled many organizations to flexibly process and gain insights from large quantities of data. These insights are typically generated from business intelligence, or OnLine Analytical Processing (OLAP) queries. Hadoop has proven to be an extremely effective framework capable of providing many analytical insights and is able to solve a wide range of distributed computing problems. However, as much as Hadoop is lauded for its wide range of use cases, it is derided for its high latency in processing and returning results. A common approach to surface data insights is to run MapReduce jobs that may take several hours to complete.

Data analysis and data-driven applications are becoming increasingly important in industry, and the long query times encountered with using batch frameworks such as Hadoop are becoming increasingly intolerable. User facing applications are replacing traditional reporting interfaces as the preferred means for organizations to derive value from their datasets. In order to provide an interactive user experience with data applications, queries must complete in an order of milliseconds. Because most of these interactions revolve around data exploration and computation, organizations quickly realized that in order to support low latency queries, dedicated serving layers were necessary. Today, most of these serving layers are Relational Database Management Systems (RDBMS) or NoSQL key/value stores. Neither RDBMS nor NoSQL key/value stores are particularly designed for analytics [19], but these technologies are still frequently selected as serving layers. Solutions that involve these broad-focus technologies can be inflexible once tailored to the analytics use case, or suffer from architecture drawbacks that prevent them from returning queries fast enough to power interactive, user-facing applications [20].

An ideal data serving layer alone is often not sufficient as a complete analytics solution. In most real-world use cases, raw data cannot be directly stored in the serving layer. Raw data suffers from many imperfections and must first be processed (transformed, or cleaned) before it is usable

[17]. The drawback of this requirement is that loading and processing batch data is slow, and insights on events cannot be obtained until hours after the events have occurred.

To address the delays in data freshness caused by batch processing frameworks, numerous open-source stream processing frameworks such as Apache Storm[12], Apache Spark Streaming[25], and Apache Samza[1] have gained popularity for offering a low-latency model to ingest and process event streams at near real-time speeds. The drawback of almost all stream processors is that they do not necessarily provide the same correctness guarantees as batch processing frameworks. Events can come in days late, and may need to be corrected after the fact. Large batches of data may also need to be reprocessed when new columns are added or removed.

Combining batch processing, streaming processing, and a serving layer in a single technology stack is known as a lambda architecture[9]. In lambda architectures, data entering the system is concurrently fed to both the batch and streaming processing layer. The streaming layer is responsible for immediately processing incoming data, however, the processed data may suffer from duplicated events and other imperfections in data accuracy. The batch layer processes incoming data much slower than the streaming layer, but is able to provide accurate views of data. The serving layer merges the results from the batch and streaming layers and provides an interface for queries. Although each individual component in a lambda architecture has their own limitations, the pieces complement each other extremely well and the overall stack is robust enough to handle a wide array of data processing and querying challenges at scale.

The RADStack is an open source lambda architecture implementation meant to offer flexible, low-latency analytic queries on near real-time data. The solution combines the low latency guarantees of stream processors and the correctness and flexibility guarantees of batch processors. It also introduces a serving layer specifically designed for interactive analytics. The stack's main building blocks are Apache Kafka[11], Apache Samza, Apache Hadoop, and Druid [23], and we have found that the combination of technologies is flexible enough to handle a wide variety of processing requirements and query loads. Each piece of the stack is designed to do a specific set of things very well. This paper will cover the details and design principles of the RADStack. Our contributions are around the architecture of the stack itself, the introduction of Druid as a serving layer, and our model for unifying real-time and historical workflows.

The structure of the paper is as follows: Section 2 describes the problems and use cases that led to the creation of the RADStack. Section 3 describes Druid, the serving layer of the stack, and how Druid is built for real-time and batch data ingestion, as well as exploratory analytics. Section 4 covers the role of Samza and Hadoop for data processing, and Section 5 describes the role of Kafka for event delivery. In Section 6, we present our production metrics.

Figure 1: The components of the RADStack. Kafka acts as the event delivery endpoints. Samza and Hadoop process data to load data into Druid. Druid acts as the endpoint for queries.

Section 7 presents our experiences with running the RAD-Stack in production, and in Section 8 we discuss the related solutions.

2. BACKGROUND

The RADStack was first developed to address problems in the online advertising. In online advertising, automated systems from different organizations will place bids against one another to display users ads in the milliseconds before a webpage loads. These actions generate a tremendous volume of data. The data shown in Table 1 is an example of such data. Each event is comprised of three components: a timestamp indicating when the event occurred; a set of dimensions indicating various attributes about the event; and a set of metrics concerning the event. Organizations frequently serve this insights to this data to ad publishers through visualizations and data applications. These applications must rapidly compute drill-down and aggregates with this data, and answer questions such as “How many clicks occurred over the span of one week for publisher google.com?” or “How many impressions were seen over the last quarter in San Francisco?”. Queries over any arbitrary number of dimensions should return in a few hundred milliseconds.

As an additional requirement, user-facing applications often face highly concurrent workloads and good applications need to provide relatively consistent performance to all users. Of course, backend infrastructure also needs to be highly available. Downtime is costly and many businesses cannot afford to wait if a system is unavailable in the face of software upgrades or network failure.

To address these requirements of scale, stability, and performance, we created Druid. Druid was designed from the ground up to provide arbitrary data exploration, low latency aggregations, and fast data ingestion. Druid was also designed to accept fully denormalized data, and moves away from the traditional relational model. Since most raw data is not denormalized, it must be processed before it can be ingested and queried. Multiple streams of data had to be joined, cleaned up, and transformed before it was usable in Druid, but that was the trade-off we were willing to make in order to get the performance necessary to power an interactive data application. We introduced stream processing to our stack to provide the processing required before raw data could be loaded into Druid. Our stream processing jobs range from simple data transformations, such as id to name lookups, up to complex operations such as multi-stream joins. Pairing Druid with a stream processor enabled

flexible data processing and querying, but we still had problems with event delivery. Our events were delivered from many different locations and sources, and peaked at several million events per second. We required a high throughput message bus that could hold these events for consumption by our stream processor. To simplify data transmission for our clients, we wanted the message bus to be the single delivery endpoint for events entering our cluster.

Our stack would be complete here if real-time processing were perfect, but the open source stream processing space is still young. Processing jobs can go down for extended periods of time and events may be delivered more than once. These are realities of any production data pipeline. To overcome these issues, we included Hadoop in our stack to periodically clean up any data generated by the real-time pipeline. We stored a copy of the raw events we received in a distributed file system, and periodically ran batch processing jobs over this data. The high level architecture of our setup is shown in Figure 1. Each component is designed to do a specific set of things well, and there is isolation in terms of functionality. Individual components can entirely fail without impacting the services of the other components.

3. THE SERVING LAYER

Druid is a column-oriented data store designed for exploratory analytics and is the serving layer in the RAD-Stack. A Druid cluster consists of different types of nodes and, similar to the overall design of the RADStack, each node type is instrumented to perform a specific set of things well. We believe this design separates concerns and simplifies the complexity of the overall system. To solve complex data analysis problems, the different node types come together to form a fully working system. The composition of and flow of data in a Druid cluster are shown in Figure 2.

3.1 Segments

Data tables in Druid (called “data sources”) are collections of timestamped events and partitioned into a set of segments, where each segment is typically 5–10 million rows. Segments represent the fundamental storage unit in Druid and Druid queries only understand how to scan segments.

Druid always requires a timestamp column as a method of simplifying data distribution policies, data retention policies, and first level query pruning. Druid partitions its data sources into well defined time intervals, typically an hour or a day, and may further partition on values from other columns to achieve the desired segment size. The time granularity to partition segments is a function of data volume and time range. A data set with timestamps spread over a year is better partitioned by day, and a data set with timestamps spread over a day is better partitioned by hour.

Segments are uniquely identified by a data source identifier, the time interval of the data, and a version string that increases whenever a new segment is created. The version string indicates the freshness of segment data; segments with later versions have newer views of data (over some time range) than segments with older versions. This segment metadata is used by the system for concurrency control; read operations always access data in a particular time range from the segments with the latest version identifiers for that time range.

Druid segments are stored in a column orientation. Given that Druid is best used for aggregating event streams, the

advantages of storing aggregate information as columns rather than rows are well documented [2]. Column storage allows for more efficient CPU usage as only what is needed is actually loaded and scanned. In a row oriented data store, all columns associated with a row must be scanned as part of an aggregation. The additional scan time can introduce significant performance degradations [2].

Druid nodes use one thread to scan one segment at a time, and the amount of data that can be scanned in parallel is directly correlated to the number of available cores in the cluster. Segments are immutable, and hence, this no contention between reads and writes in a segment.

A single query may scan thousands of segments concurrently, and many queries may run at the same time. We want to ensure that the entire cluster is not starved out while a single expensive query is executing. Thus, segments have an upper limit in how much data they can hold, and are sized to be scanned in a few milliseconds. By keeping segment computation very fast, cores and other resources are constantly being yielded. This ensures segments from different queries are always being scanned.

Druid segments are very self-contained for the time interval of data that they hold. Column data is stored directly in the segment. Druid has multiple column types to represent various data formats. Timestamps are stored in long columns, dimensions are stored in string columns, and metrics are stored in int, float, long or double columns. Depending on the column type, different compression methods may be used. Metric columns are compressed using LZ4[3] compression. String columns are dictionary encoded, similar to other data stores such as PowerDrill[8]. Additional indexes may be created for particular columns. For example, Druid will by default create inverted indexes for string columns.

3.2 Streaming Data Ingestion

Druid real-time nodes encapsulate the functionality to ingest, query, and create segments from event streams. Events indexed via these nodes are immediately available for querying. The nodes are only concerned with events for a relatively small time range (e.g. hours) and periodically hand off immutable batches of events they have collected over this small time range to other nodes in the Druid cluster that are specialized in dealing with batches of immutable events. The nodes announce their online state and the data they serve using a distributed coordination service (this is currently Zookeeper[10]).

Real-time nodes employ a log structured merge tree[14] for recently ingested data. Incoming events are first stored in an in-memory buffer. The in-memory buffer is directly queryable and Druid behaves as a key/value store for queries on events that exist in this JVM heap-based store. The in-memory buffer is heavily write optimized, and given that Druid is really designed for heavy concurrent reads, events do not remain in the in-memory buffer for very long. Real-time nodes persist their in-memory indexes to disk either periodically or after some maximum row limit is reached. This persist process converts data stored in the in-memory buffer to the column oriented segment storage format described in Section 3.1. Persisted segments are memory mapped and loaded to off-heap memory such that they can still be queried. This is illustrated in Figure 4. Data is continuously queryable during the persist process.

Real-time ingestion in Druid is self-throttling. If a significant spike occurs in event volume from the upstream event producer, there are a few safety mechanisms built in. Recall that events are first stored in an in-memory buffer and persists can occur when a maximum configurable row limit

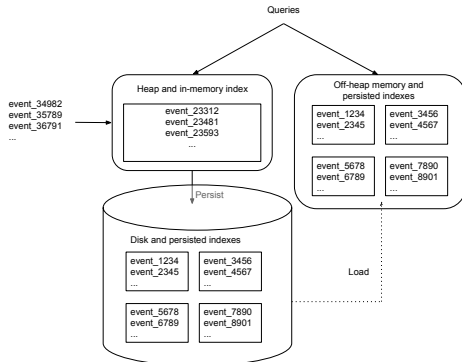

Figure 3: Real-time nodes write events to a write optimized in-memory index. Periodically, events are persisted to disk, converting the write optimized format to a read optimized one. On a periodic basis, persisted indexes are then merged together and the final segment is handed off. Queries will hit both the in-memory and persisted indexes.

is reached. Spikes in event volume should cause persists to occur more often and not overflow the in-memory buffer. However, the process of building a segment does require time and resources. If too many concurrent persists occur, and if events are added to the in-memory buffer faster than they can be removed through the persist process, problems can still arise. Druid sets a limit on the maximum number of persists that can occur at a time, and if this limit is reached, Druid will begin to throttle event ingestion. In this case, the onus is on the upstream consumer to be resilient in the face of increasing backlog.

Real-time nodes store recent data for a configurable period of time, typically an hour. This period is referred to as the segment granularity period. The nodes employ a sliding window to accept and reject events and use the wall-clock time as the basis of the window. Events within a range of the node's wall-clock time are accepted, and events outside this window are dropped. This period is referred to as the window period and typical window periods are 10 minutes in length. At the end of the segment granularity period plus the window period, a real-time node will hand off the data it has collected during the segment granularity period. The use of the window period means that delayed events may be dropped. In practice, we see that these occurrences are rare, but they do occur. Druid's real-time logic does not guarantee exactly once processing and is instead best effort. The lack of exactly once processing in Druid is one of the motivations for requiring batch fixup in the RADStack.

For further clarification, consider Figure 4. Figure 4 illustrates the operations of a real-time node. The node starts at 13:37 and, with a 10 minute window period, will only accept events for a window between 13:27 and 13:47. When the first events are ingested, the node announces that it is serving a segment for an interval from 13:00 to 14:00. Every 10 minutes (the persist period is configurable), the node will flush and persist its in-memory buffer to disk. Near the end of the hour, the node will likely see events for 14:00 to 15:00. When this occurs, the node prepares to serve data for the

next hour and creates a new in-memory buffer. The node then announces that it is also serving a segment from 14:00 to 15:00. At 13:10, which is the end of the hour plus the window period, the node begins the hand off process.

3.3 Hand off

Real-time nodes are designed to deal with a small window of recent data and need periodically hand off segments they've built. The hand-off process first involves a compaction step. The compaction process finds all the segments that were created for a specific interval of time (for example, all the segments that were created by intermediate persists over the period of an hour). These segments are merged together to form a final immutable segment for handoff.

Handoff occurs in a few steps. First, the finalized segment is uploaded to a permanent backup storage, typically a distributed file system such as S3 [5] or HDFS [16], which Druid refers to as "deep storage". Next, an entry is created in the metadata store (typically a RDBMS such as MySQL) to indicate that a new segment has been created. This entry in the metadata store will eventually cause other nodes in the Druid cluster to download and serve the segment. The real-time node continues to serve the segment until it notices that the segment is available on Druid historical nodes, which are nodes that are dedicated to serving historical data. At this point, the segment is dropped and unannounced from the real-time node. The entire handoff process is fluid; data remains continuously queryable throughout the entire handoff process. Segments created by real-time processing are versioned by the start of the segment granularity interval.

3.4 Batch Data Ingestion

The core component used by real-time ingestion is a hash map that can be incrementally populated and finalized to create an immutable segment. This core component is shared across both real-time and batch ingestion. Druid has built in support for creating segments by leveraging Hadoop and running MapReduce jobs to partition data for segments. Events can be read in one at a time directly from static files in a "streaming" fashion.

Similar to the real-time ingestion logic, segments created through batch ingestion are directly uploaded to deep storage. Druid's Hadoop-based batch indexer will also create an entry in the metadata storage once all segments have been created. The version of the segments created by batch ingestion are based on the time the batch processing job started at.

3.5 Unifying Views

When new entries are created in the metadata storage, they will eventually be noticed by Druid coordinator nodes. Druid coordinator nodes poll the metadata storage for what segments should be loaded on Druid historical nodes, and compare the result with what is actually loaded on those nodes. Coordinator nodes will tell historical nodes to load new segments, drop outdated segments, and move segments across nodes.

Druid historical nodes are very simple in operation. They know how to load, drop, and respond to queries to scan segments. Historical nodes typically store all the data that is older than an hour (recent data lives on the real-time node). The real-time handoff process requires that a historical must first load and begin serving queries for a segment

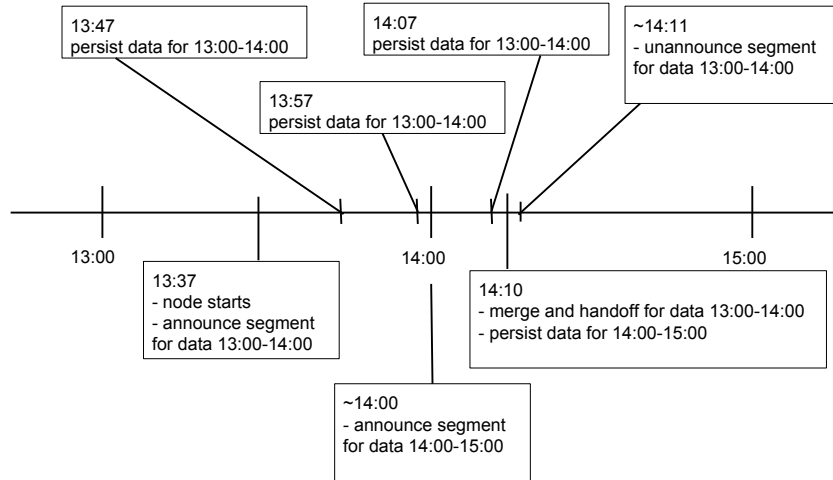

Figure 4: The node starts, ingests data, persists, and periodically hands data off. This process repeats indefinitely. The time periods between different real-time node operations are configurable.

before that segment can be dropped from the real-time node. Since segments are immutable, the same copy of a segment can exist on multiple historical nodes and real-time nodes. Most nodes in typical production Druid clusters are historical nodes.

To consolidate results from historical and real-time nodes, Druid has a set of broker nodes which act as the client query endpoint. Broker nodes in part function as query routers to historical and real-time nodes. Broker nodes understand the metadata published in distributed coordination service (Zookeeper) about what segments are queryable and where those segments are located. Broker nodes route incoming queries such that the queries hit the right historical or real-time nodes. Broker nodes also merge partial results from historical and real-time nodes before returning a final consolidated result to the caller.

Broker nodes maintain a segment timeline containing information about what segments exist in the cluster and the version of those segments. Druid uses multi-version concurrency control to manage how data is extracted from segments. Segments with higher version identifiers have precedence over segments with lower version identifiers. If two segments exactly overlap for an interval, Druid only considers the data from the segment with the higher version. This is illustrated in Figure 5

Segments are inserted into the timeline as they are announced. The timeline sorts the segment based on their data interval in a data structure similar to an interval tree. Lookups in the timeline will return all segments with intervals that overlap the lookup interval, along with interval ranges for which the data in a segment is valid.

Brokers extract the interval of a query and use it for lookups into the timeline. The result of the timeline is used to remap the original query into a set of specific queries for the actual historical and real-time nodes that hold the pertinent query data. The results from the historical and real-time nodes are finally merged by the broker, which returns the final result to the caller.

The coordinator node also builds a segment timeline for

Figure 5: Druid utilizes multi-version concurrency control and reads data from segments with the latest version for a given interval. Segments that are that completely overshadowed are ignored and eventually automatically dropped from the cluster.

segments in the cluster. If a segment is completely overshadowed by one or more segments, it will be flagged in this timeline. When the coordinator notices overshadowed segments, it tells historical nodes to drop these segments from the cluster.

4. THE PROCESSING LAYER

Although Druid can ingest events that are streamed in one at a time, data must be denormalized beforehand as Druid cannot yet support join queries. Furthermore, real world data must often be transformed before it is usable by an application.

4.1 Stream Processing

Stream processors provide infrastructure to develop processing logic for unbounded sequences of messages. We use Apache Samza as our stream processor, although other technologies are viable alternatives (we initially chose Storm, but have since switched to Samza). Samza provides an API to write jobs that run over a sequence of tuples and perform operations over those tuples in a user-defined way. The input to each job is provided by Kafka, which can also act as

Figure 6: Ad impressions and clicks are recorded in two separate streams. An event we want to join is located in two different Kafka partitions on two different topics.

Figure 7: A shuffle operation ensures events to be joined at stored in the same Kafka partition.

a sink for the output of the job. Samza jobs are executed in a resource management and task execution framework such as YARN[21]. It is beyond the scope of this paper to go into the full details of Kafka/YARN/Samza interactions, but more information is available in other literature[1]. We will instead focus on how we leverage this framework for processing data for analytic use cases.

On top of Samza infrastructure, we introduce the idea of a “pipeline”, which is a grouping for a series of related processing stages where “upstream” stages produce messages that are consumed by “downstream” stages. Some of our jobs involve operations such as renaming data, inserting default values for nulls and empty strings, and filtering data. One pipeline may write to many data sources in Druid.

To understand a real-world pipeline, let’s consider an example from online advertising. In online advertising, events are generated by impressions (views) of an ad and clicks of an ad. Many advertisers are interested in knowing how many impressions of an ad converted into clicks. Impression streams and click streams are almost always generated as separate streams by ad servers. Recall that Druid does not support joins at query time, so the events must be generated at processing time. An example of data generated by these two event streams is shown in Figure 6. Every event has a unique impression id that identifies the ad served. We use this id as our join key.

The first stage of the Samza processing pipeline is a shuffle step. Events are written to a keyed Kafka topic based on the hash of an event’s impression id. This ensures that the events that need to be joined are written to the same Kafka topic. YARN containers running Samza tasks may read from one or more Kafka topics, so it is important Samza task for joins actually has both events that need to be joined. This is shuffle stage is shown in Figure 7.

Figure 8: The join operation adds a new field, “is_clicked”.

Figure 9: The streaming processing data pipeline.

The next stage in the data pipeline is to actually join the impression and click events. This is done by another Samza task that creates a new event in the data with a new field called “is_clicked”. This field is marked as “true” if an impression event and a click event with the same impression id are both present. The original events are discarded, and the new event is send further downstream. This join stage shown in Figure 8

The final stage of our data processing is to enhance the data. This stage cleans up faults in data, and performs lookups and transforms of events. Once data is cleaned, it is ready to be delivered to Druid for queries. The total streaming data processing pipeline is shown in Figure 9.

The system we have designed is not perfect. Because we are doing windowed joins and because events cannot be buffered indefinitely, not all joins are guaranteed to complete. If events are substantially delayed and do not arrive in the allocated window period, they will not be joined. In practice, this generally leads to one “primary” event continuing through the pipeline and other secondary events with the same join key getting dropped. This means that our stream processing layer is not guaranteed to deliver 100% accurate results. Furthermore, even without this restriction, Samza does not offer exactly-once processing semantics. Problems in network connectivity or node failure can lead to duplicated events. For these reasons, we run a separate batch pipeline that generates a more accurate transformation of the ingested data.

The final job of our processing pipeline is to deliver data to Druid. For high availability, processed events from Samza are transmitted concurrently to two real-time nodes. Both nodes receive the same copy of data, and effectively act as replicas of each other. The Druid broker can query for either copy of the data. When handoff occurs, both real-time nodes race to hand off the segments they’ve created. The segment that is pushed into deep storage first will be the one that is used for historical querying, and once that segment is loaded on the historical nodes, both real-time nodes will drop their

versions of the same segment.

4.2 Batch Processing

Our batch processing pipeline is composed of a multi-stage MapReduce[4] pipeline. The first set of jobs mirrors our stream processing pipeline in that it transforms data and joins relevant events in preparation for the data to be loaded into Druid. The second set of jobs is responsible for directly creating immutable Druid segments. The indexing code for both streaming and batch ingestion in Druid is shared between the two modes of ingestion. These segments are then uploaded to deep storage and registered with the metadata store. Druid will proceed to load the batch generated segments.

The batch process typically runs much less frequently than the real-time process, and may run many hours or even days after raw events have been delivered. The wait is necessary for severely delayed events, and to ensure that the raw data is indeed complete.

Segments generated by the batch process are versioned by the start time of the process. Hence, segments created by batch processing will have a version identifier that is greater than segments created by real-time processing. When these batch created segments are loaded in the cluster, they atomically replace segments created by real-time processing for their processed interval. Hence, soon after batch processing completes, Druid queries begin reflecting batch-originated data rather than real-time-originated data.

We use the streaming data pipeline described in Section 4.1 to deliver immediate insights on events as they are occurring, and the batch data pipeline described in this section to provide an accurate copy of the data. The batch process typically runs much less frequently than the real-time process, and may run many hours or even days after raw events have been delivered. The wait is necessary for severely delayed events, and to ensure that the raw data is indeed complete.

5. THE DELIVERY LAYER

In our stack, events are delivered over HTTP to Kafka. Events are transmitted via POST requests to a receiver that acts as a front for a Kafka producer. Kafka is a distributed messaging system with a publish and subscribe model. At a high level, Kafka maintains events or messages in categories called topics. A distributed Kafka cluster consists of numerous brokers, which store messages in a replicated commit log. Kafka consumers subscribe to topics and process feeds of published messages.

Kafka provides functionality isolation between producers of data and consumers of data. The publish/subscribe model works well for our use case as multiple consumers can subscribe to the same topic and process the same set of events. We have two primary Kafka consumers. The first is a Samza job that reads messages from Kafka for stream processing as described in Section 4.1. Topics in Kafka map to pipelines in Samza, and pipelines in Samza map to data sources in Druid. The second consumer reads messages from Kafka and stores them in a distributed file system. This file system is the same as the one used for Druid’s deep storage, and also acts as a backup for raw events. The purpose of storing raw events in deep storage is so that we can run batch processing jobs over them at any given time. For example, our stream processing layer may choose to not include certain columns when it first processes a new pipeline. If we want

Data Source	Dimensions	Metrics
a	25	21
b	30	26
c	71	35
d	60	19
e	29	8
f	30	16
g	26	18
h	78	14

Table 2: Characteristics of production data sources.

to include these columns in the future, we can reprocess the raw data to generate new Druid segments.

Kafka is the single point of delivery for events entering our system, and must have the highest availability. We replicate our Kafka producers across multiple datacenters. In the event that Kafka brokers and consumers become unresponsive, as long as our HTTP endpoints are still available, we can buffer events on the producer side while recovering the system. Similarly, if our processing and serving layers completely fail, we can recover by replaying events from Kafka.

6. PERFORMANCE

Druid runs in production at several organizations, and to briefly demonstrate its performance, we have chosen to share some real world numbers for one of the larger production clusters. We also include results from synthetic workloads on TPC-H data.

6.1 Query Performance in Production

Druid query performance can vary significantly depending on the query being issued. For example, sorting the values of a high cardinality dimension based on a given metric is much more expensive than a simple count over a time range. To showcase the average query latencies in a production Druid cluster, we selected 8 frequently queried data sources, described in Table 2.

Approximately 30% of queries are standard aggregates involving different types of metrics and filters, 60% of queries are ordered group bys over one or more dimensions with aggregates, and 10% of queries are search queries and metadata retrieval queries. The number of columns scanned in aggregate queries roughly follows an exponential distribution. Queries involving a single column are very frequent, and queries involving all columns are very rare.

- There were approximately 50 total data sources in this particular cluster and several hundred users issuing queries.
- There was approximately 10.5TB of RAM available in this cluster and approximately 10TB of segments loaded. Collectively, there are about 50 billion Druid rows in this cluster. Results for every data source is not shown.
- This cluster uses Intel® Xeon® E5-2670 processors and consists of 1302 processing threads and 672 total cores (hyperthreaded).
- A memory-mapped storage engine was used (the machine was configured to memory map the data instead of loading it into the Java heap.)

Query latencies are shown in Figure 10. Across all the various data sources, average query latency is approximately 550 milliseconds, with 90% of queries returning in less than

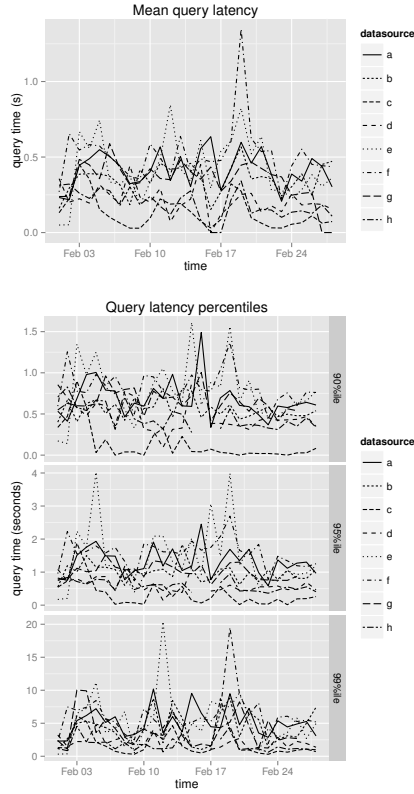

Figure 10: Query latencies of production data sources.

1 second, 95% in under 2 seconds, and 99% of queries returning in less than 10 seconds. Occasionally we observe spikes in latency, as observed on February 19, where network issues on the broker nodes were compounded by very high query load on one of our largest data sources.

6.2 Query Benchmarks on TPC-H Data

We also present Druid benchmarks on TPC-H data. Most TPC-H queries do not directly apply to Druid, so we selected queries more typical of Druid’s workload to demonstrate query performance. In Figure 11, we present our results compared again Google BigQuery, which is Google Dremel[13]. The Druid results were ran on a 24 vCPU, 156 GB Google Compute Engine instance (2.2 GHz Intel Xeon E5 v4 Broadwell) and the BigQuery results were run through Google’s web interface. In our results, Druid performed from 2-20x faster than BigQuery.

Our Druid setup used Amazon EC2 m3.2xlarge instance types (Intel® Xeon® E5-2680 v2 @ 2.80GHz) for historical nodes and c3.2xlarge instances (Intel® Xeon® E5-2670 v2 @ 2.50GHz) for broker nodes.

We benchmarked Druid’s scan rate at 53,539,211 rows/second/core for `select count(*)` equivalent query over a given time interval and 36,246,530 rows/second/core for a `select sum(float)` type query.

6.3 Data Ingestion Performance

To showcase the ingestion latency of the RADStack, we selected the top seven production datasources in terms of

Figure 11: Druid benchmarked against Google BigQuery – 100GB TPC-H data.

Data Source	Dimensions	Metrics	Peak Events/s
d1	34	24	218123
d2	36	24	172902
d3	46	21	170264
d4	40	17	94064
d5	41	23	68104
d6	31	31	64222
d7	29	8	30048

Table 3: Characteristics of production data sources.

peak events ingested per second for early 2015. These data-sources are described in Table 3. Our production ingestion setup used over 40 nodes, each with 60GB of RAM and 32 cores (12 x Intel®Xeon®E5-2670). In this setup, many other Druid related ingestion tasks were running concurrently on the machines. Each pipeline for each datasource involved transforms and joins.

Ingestion latency is heavily dependent on the complexity of the data set being ingested. The data complexity is determined by the number of dimensions in each event, the number of metrics in each event, and the types of aggregations we want to perform on those metrics. With the most basic data set (one that only has a timestamp column), our setup can ingest data at a rate of 800,000 events/second/core, which is really just a measurement of how fast we can de-serialize events. At peak, a single node was able to process 62259 events/second. The total peak events per second was 840500. The median events per second was 590100. The first and third quantiles were 487000 events/s and 663200 events/s respectively.

7. PRODUCTION EXPERIENCES

7.1 Experiences with Druid

7.1.1 Query Patterns

Druid is often used for exploratory analytics and reporting, which are two very distinct use cases. Exploratory analytic workflows provide insights by progressively narrowing down a view of data until an interesting observation is made. Users tend to explore short intervals of recent data. In the

reporting use case, users query for much longer data intervals, and the volume of queries is generally much less. The insights that users are looking for are often pre-determined.

7.1.2 Multitenancy

Expensive concurrent queries can be problematic in a multitenant environment. Queries for large data sources may end up hitting every historical node in a cluster and consume all cluster resources. Smaller, cheaper queries may be blocked from executing in such cases. We introduced query prioritization to address these issues. Each historical node is able to prioritize which segments it needs to scan. Proper query planning is critical for production workloads. Thankfully, queries for a significant amount of data tend to be for reporting use cases and can be de-prioritized. Users do not expect the same level of interactivity in this use case as they do when they are exploring data.

7.1.3 Node Failures

Single node failures are common in distributed environments, but many nodes failing at once are not. If historical nodes completely fail and do not recover, their segments need to be reassigned, which means we need excess cluster capacity to load this data. The amount of additional capacity to have at any time contributes to the cost of running a cluster. From our experiences, it is extremely rare to see more than 2 nodes completely fail at once and hence, we leave enough capacity in our cluster to completely reassign the data from 2 historical nodes.

7.2 Experiences with Ingestion

7.2.1 Multitenancy

Before moving our streaming pipeline to Samza, we experimented with other stream processors. One of the biggest pains we felt was around multi-tenancy. Multiple pipelines may contend for resources, and it is often unclear how various jobs impact one another when running in the same environment. Given that each of our pipelines is composed of different tasks, Samza was able to provide per task resource isolation, which was far easier to manage than per application resource isolation.

7.3 Operational Monitoring

Proper monitoring is critical to run a large scale distributed cluster, especially with many different technologies. Each Druid node is designed to periodically emit a set of operational metrics. These metrics may include system level data such as CPU usage, available memory, and disk capacity, JVM statistics such as garbage collection time, and heap usage, or node specific metrics such as segment scan time, cache hit rates, and data ingestion latencies. Druid also emits per query metrics so we can examine why a particular query may be slow. We've also added functionality to periodically emit metrics from Samza, Kafka, and Hadoop. We emit metrics from our production RADStack and load them into a dedicated metrics RADstack. The metrics cluster is used to explore the performance and stability of the production cluster. This dedicated metrics cluster has allowed us to find numerous production problems, such as gradual query speed degradations, less than optimally tuned hardware, and various other system bottlenecks.

8. RELATED WORK

8.1 Hybrid Batch/Streaming Workflows

Spark[24] is a cluster computing framework optimized for iterative workflows. Spark Streaming is a separate project that converts sequences of tuples into immutable micro-batches. Each micro-batch can be processed using the underlying Spark framework. Spark SQL is a query optimization layer that can sit on top of Spark and issue SQL queries, along with Spark's native API. Druid's approach to querying is quite different and Druid instead builds immutable indexed data structures optimized for low latency OLAP queries, and does not leverage lineage in its architecture. The RADStack can theoretically be composed of Spark and Spark Streaming for processing, Kafka for event delivery, and Druid to serve queries.

8.2 Druid and Other Data Stores

Druid builds on many of the same principles as other distributed columnar data stores[7], and in-memory databases such as SAP's HANA[6] and VoltDB[22]. These data stores lack Druid's low latency ingestion characteristics. Druid also has native analytical features baked in, similar to ParAccel[15], however, Druid allows system wide rolling software updates with no downtime.

Druid is similar to C-Store[18] in that it has two subsystems, a read-optimized subsystem in the historical nodes and a write-optimized subsystem in real-time nodes. Real-time nodes are designed to ingest a high volume of append heavy data, and do not support data updates. Unlike the two aforementioned systems, Druid is meant for OLAP transactions and not OLTP transactions.

9. CONCLUSIONS AND FUTURE WORK

In this paper we presented the RADStack, a collection of complementary technologies that can be used together to power interactive analytic applications. The key pieces of the stack are Kafka, Samza, Hadoop, and Druid. Druid is designed for exploratory analytics and is optimized for low latency data exploration, aggregation, and ingestion, and is well suited for OLAP workflows. Samza and Hadoop complement Druid and add data processing functionality, and Kafka enables high throughput event delivery problem.

We believe that in later iterations of this work, batch processing may not be necessary. As open source technologies mature, the existing problems around exactly-once processing will eventually be solved. The Druid, Samza and Kafka communities are working on exactly once, lossless processing for their respective systems, and in the near future, the same guarantees that the RADStack provides right now should be available using only these technologies.

10. ACKNOWLEDGMENTS

Druid, Samza, Kafka, and Hadoop could not have been built the assistance of their respective communities. We want to thank everyone that contributes to open source for their invaluable support.
